In this paper, we will discuss the prospects of deducing the proton-air cross section from fluorescence telescope measurements of extensive air showers. As it is not possible to observe the point of first interaction X_1 directly, other observables closely linked to X_1 must be inferred from the longitudinal profiles. This introduces a dependence on the models used to describe the shower development. The most straightforward candidate for a good correlation to X_1 is the depth of shower maximum $X_{\max}$. We will discuss the sensitivity of an $X_{\max}$ -based analysis on $\sigma_{\text{p-air}}$ and quantify the systematic uncertainties arising from the model dependence, parameters of the reconstruction method itself and a possible non-proton contamination of the selected shower sample.

1. Introduction

One of the most important parameter needed for interpretation of air shower measurements is the proton-air cross section $\sigma_{\text{p-air}}$, which is not well known at cosmic ray energies. Collider measurements of the proton-(anti)proton cross section have to be extrapolated over a wide energy range to be used in models of nuclear effects to predict the proton-air cross section at ultra high energies. On the other hand, it might be possible to measure $\sigma_{\text{p-air}}$ by analyzing extensive air showers (EAS).

The point of first interaction in slant depth X_1 follows the exponential distribution

$$\frac{dP(X_1)}{dX_1} = \frac{1}{\lambda_{\text{p-air}}} \cdot e^{-X_1/\lambda_{\text{p-air}}}. \quad (1)$$

The cross section $\sigma_{\text{p-air}}$ is related to the absorption length $\lambda_{\text{p-air}}$ as $\lambda_{\text{p-air}} = M_{\text{mean}}/\sigma_{\text{p-air}}$, with M_{mean} being the mean mass of a target (air) particle.

The depth and characteristics of the first interaction of the primary cosmic ray particle with a molecule of the atmosphere determines to a large extent the resulting shower shape. This implies strong correlations of the first interaction with experimentally observable parameters of the shower.

Several air shower experiments have provided measured values of $\sigma_{\text{p-air}}$ by exploiting correla-

tions of X_1 with observables found by using air shower simulations [1,2,3,4,5]. Of course, these results depend strongly on the used simulations and especially on the chosen high energy hadronic interaction model [6,7].

The HiRes collaboration proposed a new technique which appeared to be almost independent of the hadronic interaction model [8]. The idea is to decompose the measured distribution of shower maxima $dP(X_{\max})/dX_{\max}$ into the two independent distributions of X_1 and ΔX with

$$X_{\max} = X_1 + \Delta X. \quad (2)$$

Using the introduced ΔX one can express the $X_{\max}$ distribution as folding integral

$$P(X_{\max}) = \int_0^\infty dX_1 P(X_1) \cdot P(\Delta X|X_1) \quad (3)$$

of the X_1 and ΔX distributions, whereas in the HiRes [8] approach $P(\Delta X|X_1) = P(\Delta X)$ is used.

Measuring $\sigma_{\text{p-air}}$ means to deconvolve the $X_{\max}$ distribution using a known ΔX distribution.

The distribution of ΔX needs to be inferred from simulations.

2. Simulation study

To investigate the deconvolution technique, we simulated sets of proton-induced showers of 10 EeV using CONEX [9] with the high energy

Figure 1. Left panel: Dependence of the ΔX -distribution on X_1 . Right panel: Interaction model dependence of ΔX -distribution.

interaction models QGSJET01 [10], SIBYLL2.1 [11], NEXUS3 [12], and QGSJETII.3 [13]. In addition helium, CNO and gamma-ray primaries were simulated with QGSJET01. Each set of simulations contains 200.000 events.

3. Universality of ΔX distribution

One of the important conditions for the applicability of the method proposed in [8] is the X_1 -independence of the ΔX distribution. For a given model, this is indeed the case as shown in Fig. 1 (left). The universality in X_1 has been verified for proton primaries using NEXUS3, SIBYLL2.1, QGSJETII.3, and QGSJET01 at 1 EeV and 10 EeV.

Therefore one can use

$$P(\Delta X|X_1) = P(\Delta X). \quad (4)$$

However, the resulting ΔX distribution depends strongly on the hadronic interaction model used for shower simulation (Fig. 1, right). The maximum of the ΔX distribution is shifted by up to 60 gcm^{-2} and the slope beyond the maximum changes by up to a factor of 1.36. This introduces a principal model dependence to the deconvolution technique. It can be tried to reduce this dependence by adding an additional degree of freedom, X_{shift} , which allows the ΔX distribution to

shift along the x axis

$$P(\Delta X) \rightarrow P(\Delta X + X_{\text{shift}}). \quad (5)$$

It is much more difficult to reduce the model-dependence of the shape of the ΔX distribution. This will not be discussed in this paper but we shall show the impact of this model-dependence on the resulting $\sigma_{\text{p-air}}$ reconstruction.

4. Study of the deconvolution method

For each model, a Monte Carlo data set of 50.000 events was generated and analyzed with the ΔX distributions found previously. No detector effects are considered. Two free parameters ($\lambda_{\text{p-air}}$ and X_{shift}) are fitted using χ^2 minimization and

$$\begin{aligned} \frac{dP(X_{\text{max}})}{dX_{\text{max}}} &= \int_{X_{1,\text{min}}}^{X_{1,\text{max}}} dX_1 \frac{1}{\lambda_{\text{p-air}}} e^{-X_1/\lambda_{\text{p-air}}} \\ &\times \left(\frac{dP(\Delta X + X_{\text{shift}})}{d\Delta X} \right)_{\text{model}}. \end{aligned} \quad (6)$$

The fit results are shown in Tab. 1 for all combinations of hadronic interaction models and ΔX distributions. The diagonal elements of the table represent matching models for data and ΔX . In these cases the true cross section of the input model can be retrieved very well by the convolution method. It is interesting that for models with a similar shape of the ΔX distribution

Table 1

Analysis results of $\sigma_{p\text{-air}}$ in mb for 10 EeV proton showers. The results for X_{shift} are given in g/cm^{-2} . The expected cross sections are 532 mb (QGSJET01), 612 mb (SIBYLL 2.1), 542 mb (NEXUS), and 562 mb (QGSJETII).

data	ΔX model used for reconstruction							
	QGSJET		SIBYLL		NEXUS		QGSJETII	
data model	σ_{rec}	X_{shift}	σ_{rec}	X_{shift}	σ_{rec}	X_{shift}	σ_{rec}	X_{shift}
QGSJET01	537.1$\pm$5.5	1.7 $\pm$ 0.8	465.3 $\pm$ 4.1	-29.8 $\pm$ 0.8	447.9 $\pm$ 3.2	-46.9 $\pm$ 0.8	467.6 $\pm$ 3.7	-19.6 $\pm$ 0.7
SIBYLL	802.8 $\pm$ 12	36.1 $\pm$ 0.7	609.2$\pm$5.7	0.7 $\pm$ 0.5	572.8 $\pm$ 4.5	-17.4 $\pm$ 0.5	613.3 $\pm$ 5.7	10.6 $\pm$ 0.5
NEXUS	749.9 $\pm$ 10	55.1 $\pm$ 1.2	569.1 $\pm$ 3.9	19.5 $\pm$ 0.9	543.1$\pm$4.0	1.5 $\pm$ 0.5	576.5 $\pm$ 4.6	29.5 $\pm$ 0.8
QGSJETII	697.1 $\pm$ 8.2	27.0 $\pm$ 0.8	553.2 $\pm$ 4.3	-7.5 $\pm$ 0.6	521.6 $\pm$ 3.7	-26.1 $\pm$ 0.3	562.3$\pm$4.4	2.1 $\pm$ 0.4

(QGSJETII and SIBYLL) the reconstruction still works rather well, whereas for combinations of models which have a very different shape of ΔX (QGSJET and NEXUS) the results differ up to 200 mb.

4.1. Importance of fit range

The reconstructed value of $\sigma_{p\text{-air}}$ is very sensitive to the chosen starting point of the fit range, as shown in Fig. 2 (left). The reason for this is the introduced X_{shift} parameter which needs the peak of the X_{max} distribution to be restricted. To fit only the slope after the peak of the X_{max} distribution is not sufficient if X_{shift} is treated as free parameter.

Restricting the end point of the fitting range mainly increases the statistical uncertainty of the fit result. The true value of $\sigma_{p\text{-air}}^{\text{true}}$ is still within the statistical errors of the reconstructed values (see Fig. 2, right).

4.2. Impact of other elements

If the selected showers do contain a fraction of light elements other than protons, the shape of the measured X_{max} distribution will be altered. A possible contribution of helium will mostly distort the region of the peak of the X_{max} distribution. Since the peak of the X_{max} distribution is important for the fit itself, the reconstruction of $\sigma_{p\text{-air}}$ is affected (Fig. 3, top)

Contamination with CNO showers mainly influences the rising edge of the X_{max} distribution. The impact on the fit result can be limited by shifting the starting point of the fit range more towards the peak of the distribution. Using a short fit range, the effect on the reconstruction of $\sigma_{p\text{-air}}$ can be neglected for small fractions of CNO (Fig. 3, middle).

4.3. Impact of gamma-ray primaries

Gamma-ray primaries produce an X_{max} distribution which is shifted to higher X_{max} by about 200 g/cm^2 with respect to protons. Therefore the influence of gamma-ray showers can be reduced by setting the end of the fitting range appropriately (Fig. 3, bottom). Nevertheless already a small contribution of gamma-rays does affect the X_{max} distribution significantly because of the low number of proton events at high X_{max} . It should be noted that even if cosmic ray sources would accelerate only protons, a small fraction of gamma-rays is expected due to the GZK energy loss process [14].

5. Summary

The folding integral method would be very powerful given the true ΔX distribution is known. Input cross sections can be reconstructed within statistical uncertainties of a few mb. Unfortunately, the ΔX distribution does depend on the high energy hadronic interaction model used during air shower simulation. The ΔX model dependence can be reduced by adding a new degree of freedom X_{shift} to the fit but it still amounts up to ~ 100 mb. On the other hand, treating X_{shift} as free parameter increases the sensitivity of $\sigma_{p\text{-air}}$ to a possible helium contamination of the X_{max} distribution. Medium mass cosmic ray primaries have only limited influence on the reconstructed $\sigma_{p\text{-air}}$. Even a small fraction of gamma-ray primaries has a significant impact on the reconstruction results.

To use the folding integral method for a reliable cross section measurement, the model dependence of the ΔX distribution has to be reduced significantly.

Figure 2. Impact of the begin (left panel) and the end (right panel) of the fit range of the $X_{\max}$ distribution (pure proton composition at 10 EeV). On the x axis the distance to the peak of the $X_{\max}$ distribution is shown. The horizontal lines denote the true value of $\sigma_{\text{p-air}}^{\text{true, model}}$ for each interaction model.
